20.1 INTRODUCTION

Many regional, urban and high-speed inter-urban rail networks worldwide are electrified, to provide the motive power for trains (Figure 20.1).

The electrification system serves as the contact interface for current collection by each train, and in a.c. electrified railways as the means to distribute power. In general, one of two philosophies are followed: an overhead catenary above the track, with power collection by a pantograph; or conductor-rail electrification, with current collection via contact shoes on a surface of a special metallic conductor laid close to the running rails. The latter arrangement is most commonly used for d.c. traction, while the former arrangement is used for a.c. and d.c. traction. Some rail routes have dual overhead and conductor-rail electrification to facilitate route sharing by different rail operators.

Overhead catenaries are generally considered to be safer, as they are above the track, out of reach of rail personnel and the public. They are the only way in which a traction feed at high voltages can be engineered. They provide a single-phase a.c. supply with a voltage in the range of 11kV-50kV with respect to the running rails, although 1.5kV and 3kV d.c. catenaries are predominant in some

Figure 20.1: Modern high-speed a.c. electric inter-urban train
countries. When a conductor-rail system is used, the supply voltage is generally 600V to 1700V d.c.

This Chapter covers protection associated with HV overhead a.c. catenary electrification. Due to the nature of many rail routes and the limited electrical clearances (especially where an existing non-electrified route is to be electrified), catenary faults are common. A typical fault rate is one fault per year per route kilometre of track. The relatively high fault rate, coupled with the high mechanical tension in the contact wire (typically 6-20kN) demands fast fault clearance. Should a fault not be cleared quickly, the conductors that form the catenary may break due to intense overheating, with the consequent risk of further severe damage caused by moving trains and lengthy disruption to train services.

20.2 PROTECTION PHILOSOPHY

The application of protection to electrical power transmission schemes is biased towards security whilst ensuring dependability only for the most severe faults within the protected circuit. Being too adventurous with the application of remote back-up protection should be avoided, since the consequences of unwanted tripping are serious.

In the case of electrified railways, there is a high probability that sustained electrical faults of any type (high resistance, remote breaker/protection failure etc.) may be associated with overhead wire damage or a faulty traction unit. Fallen live wires caused by mechanical damage or accident represent a greater safety hazard with railways, due to the higher probability of people being close by (railway personnel working on the track, or passengers). Traction unit faults are a fire hazard and a safety risk to passengers, especially in tunnels. For these reasons, there will be a bias towards dependability of back-up protection at the expense of security. The consequences of an occasional unwanted trip are far more acceptable (the control centre simply recloses the tripped CB, some trains are delayed while the control centre ensures it is safe to reclose) than the consequences of a failure to trip for a fallen wire or a traction unit fault.

20.3 CLASSICAL SINGLE-PHASE FEEDING

Classical single-phase a.c. railway electrification has been used since the 1920’s. Earlier systems used low frequency supplies and in many countries, electrification systems using 16⅔Hz and 25Hz supplies are in use. The cost of conversion of an extensive network, with a requirement for through working of locomotives, throughout the necessary changeover period, is usually prohibitive.

Starting from Western Europe and with the influence spreading worldwide, single-phase a.c. electrification at the standard power system frequency of 50/60Hz, has become the standard. Figure 20.2 illustrates classical 25kV feeding with booster transformers (BT). The booster transformers are used to force the traction return current to flow in an aerially mounted return conductor, anchored to the back of the supporting masts (Figure 20.3). This arrangement limits traction current returning through the rails and earth in a large cross-sectional loop, thereby reducing electromagnetic interference with adjacent telecommunication circuits. A step-down transformer connected phase to phase across the Utility grid is generally the source of the traction supply. The electrical feed to the train is via the overhead catenary, with the return current flowing via the rails and then through the return conductor.

As the running rails are bonded to earth at regular intervals, they are nominally at earth potential. A single-pole circuit breaker is all that is required to disconnect the supply to the catenary in the event of a fault.

20.3.1 Classical System – Feeding Diagram

In practice, single-track railway lines are rare, and two or four parallel tracks are more common. The overhead line equipment is then comprised of two or four electrically independent catenaries, running in parallel. Figure 20.4
shows the feeding diagram for a typical two-track railway using a classical electrification system.

The infeed to the tracks in the ‘northbound’ direction is via grid transformer T1 at the Feeder Station (FS). The power is then distributed via catenaries A and B above the northbound and southbound tracks. At intervals, it is usual to parallel the two catenaries at paralleling/sub-sectioning substations, as illustrated in the Figure 20.4. Load current can then flow in the parallel paths, which reduces the impedance to the load and hence the line voltage drops. As the substation terminology implies, the provision of circuit breakers for each of the outgoing feeds to the catenaries also allows subsectioning – i.e. the ability to disconnect supply from sections of catenary, in the event of a fault, or to allow for maintenance. For a fault on catenary ‘A’ in Figure 20.4, circuit breakers A at the feeder station and at SS1 would be tripped to isolate the faulted catenary. The supply to the healthy sections of catenary B, C, D, E and F would be maintained.

**20.3.2 Classical System - Protection Philosophy**

The grid infeed transformers are typically rated at 10 to 25MVA, with a reactance of around 10% (or 2.5Ω when referred to the 25kV winding). Thus, even for a fault at the Feeder Station busbar, the maximum prospective short circuit current is low in comparison to a Utility system (typically only 10 times the rating of a single catenary). If a fault occurs further down the track, there will be the additional impedance of the catenary and return conductor to be added to the impedance of the fault loop. A typical loop impedance would be 0.6Ω/km (1Ω/mile). Account may have to be taken of unequal catenary impedances – for instance on a four-track railway, the catenaries for the two centre tracks have a higher impedance than those for the outer tracks due to mutual coupling effects. For a fault at the remote end of a protected section (e.g. Catenary section ‘A’ in Figure 20.4), the current measured at the upstream circuit breaker location (CB A at the FS) may be twice rated current. Thus at Feeder Stations, overcurrent protection can be applied, as there is a sufficient margin between the maximum continuous load current and the fault current at the remote ends of catenary sections. However, overcurrent protection is often used only as time-delayed back-up protection on railways, for the following reasons:

a. the protection needs to be discriminative, to ensure that only the two circuit breakers associated with the faulted line section are tripped. This demands that the protection should be directional, to respond only to fault current flowing into the section. At location SS1, for example, the protection for catenaries A and B would have to look back towards the grid infeed. For a fault close to the FS on catenary A, the remote end protection will measure only the proportion of fault current that flows via healthy catenary B, along the ‘hairpin’ path to SS1 and back along catenary A to the location of the fault. This fault current contribution may be less than rated load current (see Figure 20.5)
b. the prospective fault current levels at SS1, SS2 and MPSS are progressively smaller, and the measured fault currents at these locations may be lower than rated current.

c. during outages of grid supply transformers, alternative feeding may be necessary. One possible arrangement is to extend the normal feeding by closing the bus section circuit breaker at the MPSS. The prospective current levels for faults beyond the MPSS will be much lower than normal.

Overcurrent protection is detailed in Section 20.5. In addition to protection against faults, thermal protection of the catenary is required to prevent excessive contact wire sag, leading to possible dewirements. Section 20.4 details the principles of catenary thermal protection.

Distance protection has been the most proven method of protecting railway catenaries, due to its inherent ability to remain stable for heavy load current, whilst being able to discriminatively trip for quite low levels of fault current. For general details of distance protection, see Chapter 11. Figure 20.5 shows how the fault current generally lags the system voltage by a greater phase angle than is usual under load conditions, and thus the impedance phase angle measurement is an important attribute of distance relays for discriminating between minimum load impedance and maximum remote fault impedance.

20.3.3 Distance Protection Zone Reaches

Distance relays applied to a classical single-phase electrified railway system have two measurement inputs:

a. a catenary to rail voltage signal derived from a line or busbar connected voltage transformer

b. a track feeder current signal derived from a current transformer for the circuit breaker feeding the protected section

Distance relays perform a vector division of voltage by current to determine the protected circuit loop impedance (\(Z\)). Typical relay characteristics are shown in the \(R+jX\) impedance plane, Figure 20.6.

Solid faults on the catenary will present impedances to the relay along the dotted line in Figure 20.6. The illustrated quadrilateral distance relay operating zones have been set with characteristic angles to match the catenary solid-fault impedance angle, which is usually 70 to 75 degrees. Two of the zones of operation have been set as directional, with the third being semi-directional to provide back-up protection. The measured fault impedance will be lower for a fault closer to the relay location, and the relay makes a trip decision when the measured fault impedance falls within its tripping zones. Three zones of protection (shown as Z1, Z2, Z3) are commonly applied. For each zone, the forward and resistive impedance reach settings must be optimised to avoid tripping for load current, but to offer the required catenary fault coverage. All fault impedance reaches for distance zones are calculated in polar form, \(Z\angle\theta\), where \(Z\) is the reach in ohms, and \(\theta\) is the line angle setting in degrees. For railway systems, where all catenaries have a similar fault impedance angle, it is often convenient to add and subtract section impedances algebraically and treat \(Z\) as a scalar quantity.

Relays at all of the track sectioning substations (SS1, etc.) will see the reverse-looking load and regeneration areas in addition to those in the forward direction shown in Figure 20.6. The reverse-looking zones, which are mirror images of the forward-looking zones, have been omitted from the diagram for clarity.

20.3.3.1 Zone 1

The Zone 1 element of a distance relay is usually set to protect as much of the immediate catenary section as possible, without picking-up for faults that lie outside of the section. In such applications Zone 1 tripping does not need to be time-graded with the operation of other protection, as the Zone 1 reach (Z1) cannot respond to faults beyond the protected catenary section. Zone 1 tripping can be instantaneous (i.e. no intentional time delay). For an under-reaching application, the Zone 1 reach must therefore be set to account for any possible overreaching errors. These errors come from the relay, the VT’s and CT’s and inaccurate catenary impedance data. It is therefore recommended that the reach of the Zone 1 element is restricted to 85% of the protected catenary impedance, with the Zone 2 element set to cover the final 15%.

20.3.3.2 Zone 2

To allow for under-reaching errors, the Zone 2 reach (Z2)
should be set to a minimum of 115% of the protected catenary impedance for all fault conditions. This is to guarantee coverage of the remote end not covered by Zone 1. It is often beneficial to set Zone 2 to reach further than this minimum, in order to provide faster back-up protection for uncleared downstream faults. A constraining requirement is that Zone 2 does not reach beyond the Zone 1 reach of downstream catenary protection. This principle is illustrated in Figure 20.7, for a four-track system, where the local breaker for section H has failed to trip.

In order to calculate Z2 for the FS circuit breaker of protected catenary ‘A’, a fault is imagined to occur at 70% of the shortest following section. This is the closest location that unwanted overlap could occur with Z2 main protection for catenary H. The value of 70% is determined by subtracting a suitable margin for measurement errors (15%) from the nominal 85% Z1 reach for catenary H protection. The apparent impedance of the fault, as viewed from relay A at location FS is then calculated, noting that any fault impedance beyond SS1 appears to be approximately four times its actual ohmic impedance, due to the fault current paralleling along four adjacent tracks. The setting applied to the relay is the result of this calculation, with a further 15% subtracted to allow for accommodate any measurement errors at relay A location.

The equation for the maximum Zone 2 reach becomes:

\[
Z_2 = \frac{\left( Z + 0.7H \right) \times \left( A + R \right)}{R} \times 1.15
\]

where:
- \( H \) = impedance of shortest following section
- \( A \) = impedance of protected section
- \( R \) = impedance of sections B, C, D in parallel

\[ Z = \text{impedance of sections A, B, C, D in parallel} \]

The possibility of current following out and back along a hairpin path to a fault has already been discussed and it is essential that the relay does not overreach under these conditions. The feeding scenario is shown in Figure 20.8.

Figure 20.8 depicts a fault that has been cleared at one end only, with the remote end breaker for section D failing to trip. The fault is assumed to be on the lowest impedance catenary, which is an important consideration when there are more than two tracks. In a four-track system, it is usual for mutual induction to cause inner (middle) track catenaries to have a characteristic impedance that is 13% higher than for the outside tracks.

The calculation principle is similar to that for normal feeding, except that now the fault current is paralleling along three (= number of tracks minus one) adjacent tracks. The three catenaries concerned are the protected catenary A, and the remainder of the healthy catenaries (R), i.e. catenaries B and C.

The equation for the maximum hairpin Zone 2 reach becomes:

\[
Z_2 = \left( Z + 0.7D \right) \times \left( \frac{A + R}{R} \right) \times 1.15
\]

where:
- \( D \) = impedance of shortest hairpin fed section
- \( A \) = impedance of protected section
- \( R \) = impedance of sections B and C in parallel
- \( Z \) = impedance of sections A, B, C, D in parallel
To avoid overreaching for both normal feeding and hairpin fed faults, the lower of the two calculated impedances is used as the Zone 2 reach setting.

20.3.3.3 Zone 3

The Zone 3 element would usually be used to provide overall back-up protection for downstream catenary sections. The Zone 3 reach (Z3) should typically be set to at least 115% of the combined apparent impedance of the protected catenary plus the longest downstream catenary. Figure 20.9 shows the feeding considered:

The equation for the minimum Zone 3 reach (normal feeding) for Relay A becomes:

\[ Z_3 = 1.15 \times (Z + E) \times \left( \frac{A + R}{R} \right) \] 

where:

- \( E \) = impedance of longest following section
- \( A \) = protected section impedance
- \( R \) = impedance of sections B, C, D in parallel
- \( Z \) = impedance of sections A, B, C, D in parallel

It can be appreciated that hairpin feeding scenarios too must be considered, and this is depicted in Figure 20.10:

The equation for the minimum Zone 3 reach (hairpin feeding) becomes:

\[ Z_3 = 1.15 \times (Z + D) \times \left( \frac{A + R}{R} \right) \]

where:

- \( D \) = impedance of longest hairpin fed section

Further, to offset the effects of trains with regenerative braking, which would provide an additional current infeed to the fault. An additional 5% reach increase would generally be sufficient to allow for regenerative underreach.

20.3.3.4 Reverse Reaching Zones

An impedance measurement zone with reverse reach is typically applied to provide back-up protection for the local busbar at a paralleling/sectionalising substation. A typical reverse reach is 25% of the Zone 1 reach of the relay. Typically Zone 3 is set with a reverse offset to provide this protection and also so that the Zone 3 element will satisfy the requirement for Switch-on-to-Fault (SOTF) protection.

20.3.3.5 Distance zone time delay settings

The Zone 1 time delay (tZ1) is generally set to zero, giving instantaneous operation.

The Zone 2 time delay (tZ2) should be set to co-ordinate with Zone 1 fault clearance time for downstream catenaries. The total fault clearance time will consist of the downstream Zone 1 operating time plus the associated breaker operating time. Allowance must also be made for the Zone 2 elements to reset following clearance of an adjacent line fault and also for a safety margin. A typical minimum Zone 2 time delay is of the order of 150-200ms. This time may have to be adjusted where the relay is required to grade with other Zone 2 protection or slower forms of back-up protection for downstream circuits.

The Zone 3 time delay (tZ3) is typically set with the same considerations made for the Zone 2 time delay, except that the delay needs to co-ordinate with the downstream Zone 2 fault clearance. A typical minimum Zone 3 operating time would be in the region of 400ms. Again, this may need to be modified to co-ordinate with slower forms of back-up protection for adjacent circuits.
20.3.4 Load Avoidance

Figure 20.4 shows how the distance relay trip characteristics must avoid regions of the polar plot where the traction load may be present. This has historically been achieved by using shaped trip characteristics, such as the lenticular characteristic. Commencing around 1990, the benefits of applying quadrilateral characteristics were realised with the introduction of integrated circuit relays. A quadrilateral characteristic permits the resistive reach to be set independently of the required forward zone reach, which determines the position of the top line of the quadrilateral element. The resistive reach setting is then set merely to avoid the traction load impedance by a safe margin and to provide acceptable resistive fault coverage. Figure 20.11 shows how the resistive reach settings are determined:

![Figure 20.11: Resistive reach settings for load avoidance](image)

For all quadrilateral characteristics, impedance point B is the critical loading to avoid. The magnitude of the impedance is calculated from $Z = V/I$ taking the minimum operational catenary voltage and the maximum short-term catenary current. The catenary voltage is permitted to fall to 80% of nominal or less at the train location under normal operating conditions, and the short term current loading to rise to 160% of nominal – these worst-case measured values should be used when aiming to find the lowest load impedance.

The phase angle of point B with respect to the resistive axis is determined as:

$$\theta = \cos^{-1} \text{(max lagging power factor)}$$

The diagram shows how resistive reach E-F for Zone 1 has been chosen to avoid the worst-case loading by a suitable margin of 10%-20%. Zones 2 and 3 reach further, thus the effect of any angular errors introduced by CT's, VT's etc. will be more pronounced. It is therefore common to set the resistive reaches progressively marginally smaller for zones with longer reaches. A practical setting constraint to ensure that zones with long reaches are not too narrow, and not overly affected by angle measurement tolerances, is for the resistive reach not to be less than 14% of the zone reach.

20.3.5 Enhanced Modern Relay Characteristics

Figure 20.12 illustrates the polygonal distance relay characteristics of a modern numerical railway distance relay. Introduction of a $\gamma$ setting modifies the basic quadrilateral characteristic into a polygonal one, in order to optimise fault impedance coverage and load avoidance for modern railway applications.

![Figure 20.12: Polygon distance characteristics](image)

The use of the $\gamma$ setting allows a load avoidance notch to be placed within the right-hand resistive reach line of the quadrilateral. $\gamma$ is chosen to be around 10 degrees greater than the worst-case power factor load angle, limiting the resistive reach to $R_\gamma$ to avoid all load impedances. For impedance angles greater than $\gamma$, the zone resistive reach $R$ applies, and the fault arc resistive coverage is improved. This is especially beneficial for Zone 3 back-up protection of adjacent catenaries, where the apparent level of arc resistance will be raised through the effect of parallel circuit infeeds at the intervening substation.

20.3.6 Impact of Trains with Regenerative Braking

It is common for the Zone 1 characteristic to apply to the forward direction only. However, other zones may be set to have a reverse reach – see Section 20.3.3.4 for details. Another case where reverse-reaching zones may be required is where trains having regenerative braking are used. Such trains usually regenerate at a leading power factor...
to avoid the creation of overvoltages on the catenary. Where a regenerating train contributes to fault current, the fault impedance measured by distance relays may shift up to 10° greater than \( \alpha \). Some railway administrations require that the fault impedance remains within the trip characteristic, and does not stray outside the top left hand resistive boundary of the polygon. This can be obtained by setting the reverse resistive reach (\( R_{\text{bw}} \)) to be greater than the forward resistive reach (\( R_{\text{fw}} \)).

20.3.7 Other Relay Characteristics

Recent relay technology developments also allow the use of detectors for rate of change of current and voltage (di/dt and dv/dt). These detectors are used to control the time delays associated with time-delayed Zones 2 and 3, and hence obtain better discrimination between load and fault impedances. The technique is still in its infancy, but shows significant potential for the future.

20.4 CATENARY THERMAL PROTECTION

It is essential that railway catenaries remain in the correct position relative to the track, thus ensuring good current collection by train pantographs. The catenary is designed to operate continuously at a temperature corresponding to its full load rating, where heat generated is balanced with heat dissipated by radiation etc. Overtemperature conditions therefore occur when currents in excess of rating are allowed to flow for a period of time. Economic catenary design demands that the catenary rating be that of the maximum average continuous load expected. Peaks in loading due to peak-hour timetables, or trains starting or accelerating simultaneously are accommodated using the thermal capacity of the catenary - in much the same way as use is made of transformer overload capacity to cater for peak loading.

It can be shown that the temperatures during heating follow exponential time constants and a similar exponential decrease of temperature occurs during cooling. It is important that the catenary is not allowed to overheat, as this will lead to contact wire supporting arms moving beyond acceptable limits, and loss of the correct alignment with respect to the track. The period of time for which the catenary can be overloaded is therefore a function of thermal history of the catenary, degree of overload, and ambient temperature.

The tension in the catenary is often maintained by balance weights, suspended at each end of tension lengths of contact wire. Overtemperature will cause the catenary to stretch, with the balance weights eventually touching the ground. Further heating will then result in a loss of contact wire tension, and excessive sagging of the contact wire. To provide protection against such conditions, catenary thermal protection is provided.

20.4.1 Catenary Thermal Protection Method

Catenary thermal protection typically uses a current based thermal replica, using load current to model heating and cooling of the protected catenary. The element can be set with both alarm (warning) and trip stages.

The heat generated within the catenary is the resistive loss (\( PR_{x,t} \)). Thus, the thermal time characteristic used in the relay is therefore based on current squared, integrated over time. The heating leads to a temperature rise above ambient temperature, so in order to calculate the actual catenary temperature, the relay must know the ambient temperature along its' length. This can be either set as an assumed 'default' ambient temperature, or measured, typically using a temperature probe mounted externally to the substation building. However, the tension length of a contact wire may be over 1km, and traverse cuttings and tunnels - with resulting significant changes in the local ambient temperature. Therefore, the probe should ideally be mounted in a location that most accurately models the coolant air around the catenary for the majority of the protected section:

- a. if exposed to direct sunlight, then the probe should be mounted to face the sun
- b. if shaded from sunlight, such as running in a tunnel, then the probe should be mounted on an exterior wall facing away from the sun
- c. if running in a cutting, shielded from wind, the probe should be mounted in the lee of the substation
- d. if exposed to the wind, the probe should also be mounted on an exposed wall

It is virtually impossible to site the probe such as to exactly model the ambient conditions along the protected section, and thus a typical error in the allowable temperature rise of between 1°C and 3°C will result (for well-sited and poorly-sited probes, respectively). RTD and CT errors, along with relay tolerances may also introduce further errors of up to 1°C in the thermal model. Overall, the error in the temperature reading above the 20°C rated ambient could be 4°C. Therefore, relays may have a setting to compensate for such measurement tolerances, to ensure that the trip will not occur too late to prevent mechanical damage. Some relays may have an option to express the above tolerance as a percentage of the temperature at which a trip is required, rather than in absolute terms.
20.5 CATERINARY BACKUP PROTECTION

Railway systems often use overcurrent protection as time-delayed back-up protection for the main distance protection. Two different philosophies for overcurrent protection are typical:

a. definite-time overcurrent protection (DTOC)

b. back-up overcurrent protection (BUOC)

20.5.1 Definite-time Overcurrent Protection (DTOC)

This form of protection is continually in service, in parallel to the distance relay elements, either included within the same relay as the distance function, or as a separate relay. The latter approach is currently more common for installations at Feeder Stations. This is due to the perceived increase in security and reliability obtained from the redundancy of separate devices. However, the trends evident in other protection applications to provide more functionality within a single relay will in time surely apply to this area as well.

It operates on the basis of conventional definite-time overcurrent protection, as described in Chapter 9. The time settings are chosen to ensure that the distance relay elements should operate first, thus the overcurrent elements only operate if the distance elements fail, or if they are out of service for some reason.

20.5.2 Back-up Overcurrent Protection (BUOC)

This form of back-up protection is switched in service only during periods when the distance protection is out of service. A typical example is where VT supervision or a measuring circuit monitoring function detects a blown VT fuse or an MCB trip. In such instances the distance protection is automatically blocked, and the BUOC elements can be automatically brought into service, such that catenary protection is not lost.

Methods of setting overcurrent protection are covered in Chapter 9. An example of using overcurrent protection is given in Section 20.8.

20.6 AUTOTRANSMFORMER FEEDING

High-speed rail lines, with maximum speeds in excess of 200km/h (125mph) have much higher traction power demands. This is not only to cope with the peak power required for rapid acceleration to high speed, but also to cope with the steeper gradients that are commonly encountered along such routes. The total traction power per train may amount to 12-16MW, comprising two or more power cars per unit and often two units coupled together to form a complete train. The heavy load currents drawn may cause significant voltage drops across the catenary feeding impedance with a classical feeding arrangement – depending on the section length being fed and the traffic frequency (in both directions). To avoid a decrease in train performance, feeder stations and paralleling substations for classical systems would have to be sited at prohibitively short intervals. In such circumstances, especially where the route involves new construction, autotransformer feeding is normally favoured.

20.6.1 Description of Autotransformer Feeding

Autotransformer feeding uses a high voltage system comprising of a centre-tapped supply transformer, catenary wire and a feeder wire. The feeder wire is aerially mounted on insulators along the back of the overhead line masts. The running rails are connected to the centre tap of the supply transformer, and hence a train sees only half of the system voltage. Autotransformers located at intervals along the tracks ensure division of load current between catenary and feeder wires that minimises the voltage drop between the supply transformer and the train. Figure 20.13 shows autotransformer feeding for the typical 25-0-25kV system found in Western Europe.

The use of autotransformers (AT) results in distribution losses that are lower than for classical 25kV feeding, and therefore can support the use of high power 25kV traction units. Feeder substation spacing can also be much greater than if a classical feeding system is used. Fewer substations means less maintenance and reduced operating costs. Two-pole switchgear is normally used to isolate both the feeder and catenary wires in the event of a fault on either wire. However, some autotransformer systems allow single wire tripping, where separate distance protection is provided for each wire. The protection would then monitor the two 'halves' of the system independently, with Protection Zones 1 and 2 typically set to 85% and 120% of the protected
Figure 20.14: Autotransformer-fed system one-line diagram showing protection

Figure 20.15: Typical autotransformer-fed and catenary layout
circuit impedance - similar to the protection of a classical catenary system. Figure 20.13 also illustrates the distribution of load current for a train situated midway between AT locations.

The topology of the AT system is often similar to the classical system shown in Figure 20.4, except that the grid supply transformer 50kV secondary winding is wound as a centre-tapped AT winding, and ATs are connected catenary-rail-feeder at each downstream substation and at intervening locations.

Figure 20.14 shows a typical protection one-line diagram for an autotransformer-fed system, while Figure 20.15 shows the construction of the catenary system.

20.6.2 Autotransformer System Protection Philosophy

From Figure 20.13 it can be seen that that the summation \((I_c - I_f)\) at any location will be equal to the downstream traction load current. The same is true for fault current, and so physically performing this current summation, through the parallel connection of feeder and catenary CT secondary windings, or mathematically summing within a protection relay, can be the basis for autotransformer circuit protection.

To discriminate between normal load current and feeder wire or catenary faults, distance protection is commonly applied, with \((I_c - I_f)\) being the measured current. The measured voltage is generally the catenary to rail voltage. The relatively low reactance of the ATs – typically 1% on a 10MVA base – ensures that any fault voltage drop on the catenary will be proportional to the feeder wire voltage drop.

When applying zones of distance protection to AT systems, with double-pole tripping, it should be appreciated that it is not usually possible to provide fully discriminative protection. When the catenary and feeder currents are combined, the relationship between impedance and distance-to-fault is non-linear. Consequently, it is more difficult to set Zone 1 to be under-reaching and Zone 2 to be overreaching in the normal manner. The approach that is normally adopted is to set the Feeder Station distance protection to detect all faults along any track, up to, but not beyond, the Mid-Point Substation. It can be arranged that operation of any distance relay will trip all Feeder Station breakers. In the event of any fault up to the MPSS, simultaneous tripping of all the track feeder circuit breakers at the FS will cut supplies to all tracks. Where this scheme is adopted, the application of auto-reclosing is essential to restore supplies to all but the permanently faulted section of catenary and feeder. The momentum of moving trains will ensure that little speed is lost during the dead time of the auto-reclose sequences. Considerations relating to the application of auto-reclosure are detailed in Section 20.5.5. With high speed lines generally being better fenced, and having fewer overbridges and greater electrical clearances compared to classical systems, the infrequent losses of supply cause few operational problems. As tripping of circuit breakers at the FS isolates all line faults, there is then no need to have switchgear at downstream substations rated to interrupt fault current. For economy, load-breaking switches are used instead of breakers at SS1 and SS2 in Figure 20.4.

20.6.3 Distance Protection Zone Reaches

Figure 20.16 illustrates the typical locus of impedance measured at the FS, for a catenary to earth fault, at a variable location upstream of SS2, for any one track. While a similar effect exists for classically-fed systems, it is small by comparison and normally ignored. The impedance measured is defined as:

\[
Z = \frac{V_{catenary}}{(I_{catenary} - I_{feeder})}
\]

For clarity, only the impedances measured for a catenary to earth fault located upstream of SS2 are plotted. The hump-like impedance locus in Figure 20.16 has a number of identifiable trends:

a. the initial slope of the locus, in ohms/km, shown as line 'A'. This is according to the catenary-to-rail loop impedance of (the 25kV loop in Figure 20.13), since the fault current flows almost entirely in the catenary-rail loop for faults close to a feeding point

b. at AT locations, slope 'B' shows how the effective ohms/km trend is less than half the catenary-to-feeder loop impedance (the 50kV loop in Figure 20.13) due to the method of impedance measurement and due to the fault current distribution. For a catenary-earth fault located at an autotransformer, the fault current will circulate...
almost entirely in the catenary-feeder loop rather than in the catenary-rail loop. Additionally, the impedance of the catenary-feeder loop is lower than that of the catenary-rail loop, as the feeder cable is a better conductor than the rails.

c. beyond SS1, the effect of parallel feeding from other circuits between the FS and SS1 means that slope 'C' for a single circuit beyond SS1 is greater than slope 'A'. With reference to Figure 20.12, the system simulated is four track, thus the gradient of 'C' will be approximately four times that of 'A' (marginally higher than four for the inner tracks, and less than four for outer tracks).

Considerations for the setting of distance relay reaches are detailed in the following sections.

20.6.3.1 Zone 1

The Zone 1 elements of any FS distance relay should not overreach and trip for faults beyond the MPSS, when the mid-point bus section breaker is closed. If it is known that the MPSS is definitely open, then there is no real reach constraint for distance protection. However, if the mid-point breaker is closed, or no status information is communicated to the protection to control overreach, through reversion to an alternative setting group, then the relay must not trip for the lowest impedance for a fault at the MPSS busbar. Referring to Figure 20.16, this fault impedance would be $Z_{\text{min}}$ along slope B (to 15km and 7.5Ω). The applied Zone 1 setting should be restricted to 85% of this impedance, to allow for all measurement and impedance data tolerances.

A lower reach setting might be necessary to prevent unwanted tripping with aggregate magnetising inrush currents following circuit energisation. This will depend on the response of the relay elements to inrush current and to the number of AT’s applied. For relays that have immunity or reduced sensitivity to inrush currents such a constraint may not apply.

20.6.3.2 Zone 2

Allowing for under-reaching errors, the Zone 2 reach (Z2) should be set in excess of 115% of the protected line impedance for all fault conditions. The relevant impedance in Figure 20.16 would be the $Z_{\text{max}}$ peak between SS2 and MPSS. A typical value of $Z_{\text{max}}$ would be approximately 11.5Ω at 13km distance from the feeder station. If trains with regenerative braking are in service along the protected track a 20% additional reach margin would typically be applied. With the stated Zone 1 and Zone 2 setting policy, relays at the Feeder Station provide complete track protection up to the MPSS.

20.6.3.3 Zone 3

Zone 3 may be applied to provide remote back-up protection for faults beyond the MPSS, or with a longer reach to cover instances where AT’s are switched out of service, such that the effective normal feeding impedance becomes higher.

20.6.4 Distance Zone Time Delay Settings and Load Avoidance

The principles used are identical to those for classical feeding, with one exception. A short time delay of the order of 50ms may be used with the Zone 1 element if a relay without magnetising inrush restraint is used.

The relay uses $(I_c - I_f)$, which is measuring the combined load current of all trains at their pantographs. Therefore, the load impedance to avoid is that measured from catenary to rail (the '25kV' impedance in Figure 20.11).

20.6.5 Implications of using Two-Pole Switching and Auto-Reclosure

A full discussion of operational implications is beyond the scope of this Chapter, thus only the important points are listed:

a. it is usual to remove all parallelling between tracks prior to any breaker reclosing. This avoids repetitive re-tripping of healthy catenary sections as multiple track feeder circuit breakers are being reclosed after clearance of a fault on one feeder. Parallelling is removed by opening the motorised isolators at all SS and MPSS locations. Following feeder breaker reclosure, the tracks will be radially fed. A persistent fault would only result in re-tripping of the faulted track circuit breakers.

b. in the period where tracks are being radially-fed, the relays at the FS should only trip their own track circuit breakers. Cross-tripping of parallel track circuit breakers should be inhibited.

c. protection at the FS can trip for an AT fault. Since there would typically be no circuit breakers at the SS and MPSS autotransformer locations, AT protection should wait for loss of line voltage during the dead time of FS circuit breakers before initiating the opening of a local motorised disconnector switch. This action should take place within the dead time so that the faulted AT will have been disconnected before reclosure of the FS breakers.

d. with radially fed tracks, multiple shot auto-reclosing, is often applied to dislodge any debris (wildlife or other stray material) that may have caused a semi-permanent fault. Before the last auto-reclose shot, it is common to disconnect all AT’s downstream of the FS. With all AT’s and...
paralleling removed the faulted circuit distance relays would then see a linear relationship between the impedance measured and the distance to fault. The results obtained from a conventional, integral fault location algorithms would then offer rectification crews a fairly accurate estimate of where the permanent fault might be located.

e. it may be necessary to automatically increase the Zone reaches of distance relay elements before the final auto-reclose attempt to allow for the higher catenary to rail fault loop impedance up to the MPSS rather than the lower catenary-feeder loop impedance. This may be achieved by switching to an alternative setting group with Z2 set higher than previously.

20.6.6 Backup Protection

Backup protection considerations for autotransformer fed systems are similar, in principle, to those for classical systems, as described in Section 20.5.

20.7 FEEDER SUBSTATION PROTECTION

Each feeder substation comprises transformers, busbars, cables, switchgear, etc. All of these items require protection. Due to the much higher frequency of faults on the catenary system, special attention must be given to ensuring that the substation protection remains stable for catenary faults, whilst offering dependable protection for substation faults.

Other than this, there are no special requirements for the protection of feeder substation equipment and the forms of protection detailed in Chapters 9-16 are directly applicable, on a single phase basis.

20.8 EXAMPLE OF CLASSICAL SYSTEM PROTECTION

Figure 20.17 depicts a typical 25kV system, where the settings for the relay protecting track feeder TF-1 at Substation S1 are to be calculated. The inputs to the relay are derived from the track feeder CT adjacent to the circuit breaker, and from a section busbar VT at busbar S1 (a catenary-side VT would be equally suitable). The system data is given in Table 20.1. A MiCOM P438 relay is used in the example.

Table 20.1: Electrified railway system data

20.8.1 Section Impedance Data

The first step is to calculate the primary impedance for the catenary sections to be protected. Zone 1 for the relay associated with feeder TF-1 protects section 1, however the backup protection offered by Zones 2 and 3 must discriminate with downstream relays and so the impedance of sections 2, 3 and 4 needs to be calculated too. In this example each pair of catenaries runs between the common substations, and so the impedance of adjacent sections will be identical. There are situations where this is not the case, of which

a. the sections to be protected consist of four tracks

b. the two tracks follow different routes due to the geography of the route and hence may not be of the same length

c. if there is a junction within a section are three examples.

The equivalent section impedance per kilometre is given by the formula:

\[
Z_{sec/km} = \text{line impedance}/km + (\text{BT impedance}/\text{BT spacing})
\]

\[
= (0.26 + j0.68) + \left(\frac{0.051 + j0.21}{3}\right)
\]

\[
= 0.277 + j0.75Ω/km
\]

\[
= 0.8\angle69.7°Ω/km
\]
This will be rounded up to 70° as the nearest settable value of the common characteristic line angle of the relay, \( \alpha \).

Distance protection relays are often set and injection-tested in terms of the impedance on the secondary side of the CT’s/VT’s used. Therefore, it is helpful for testing if the primary impedances on the system are converted to secondary quantities. The equation to be used is:

\[
Z_{\text{sect}}' = Z_{\text{sect}} \times \frac{\text{CT ratio}}{\text{VT ratio}}
\]

where:
- \( Z_{\text{sect}} \) = system impedance referred to primary
- \( Z_{\text{sect}}' \) = system impedance referred to secondary

Hence,
\[
Z_{\text{sect}}' = Z_{\text{sect}} \times \frac{600/1}{26400/110} = Z_{\text{sect}} \times 2.5
\]

20.8.2 Section Impedance Calculations

The section impedances can be calculated as follows:

20.8.2.1 Sections 1 and 2

The impedances for sections 1 and 2 are:
- \( Z_{\text{sect}} = 12.2 \times 0.8 = 9.76 \Omega \)
- \( Z_{\text{sect}}' = 9.76 \times 2.5 = 24.4 \Omega \)

20.8.2.2 Sections 3 and 4

The impedances for sections 3 and 4 are:
- \( Z_{\text{sect}} = 13.7 \times 0.8 = 10.96 \Omega \)
- \( Z_{\text{sect}}' = 10.96 \times 2.5 = 27.4 \Omega \)

20.8.3 Zone 1 Reach Calculation for TF-1

The Zone 1 forward reach is set to be 85% of the section 1 impedance, referred to the secondary of the relay. Hence, the forward reach is calculated as
\[
Z_{1\text{fw}} = 24.4 \times 0.85 = 20.75 \Omega
\]

Zone 1 is not required to operate in the reverse direction, so the setting \( Z_{1\text{bw}} \) is set to Blocked.

20.8.4 Zone 2 Reach Calculation for TF-1

Two configurations have to be considered in the setting of the Zone 2 reach. These are:
- a. the ‘follow-on’ configuration of Figure 20.7
- b. the ‘Hairpin’ feeding configuration of Figure 20.8

The setting required is the lowest of the above two configurations.

20.8.4.1 ‘Follow-on’ configuration

Figure 20.7 shows the condition to consider, with two track feeding only for the area fed by Substation S1. Equation 20.1 is used to calculate the reach:

\[
Z_2 = \frac{(Z + 0.7E) \times (A + R)}{1.15} \times \frac{2}{R}
\]

where:
- \( Z \) = impedance of sections 1 and 2 in parallel
- \( A \) = the track section of interest, section 1
- \( R \) = parallel fault current path (section 2)
- \( E \) = shortest following section (3 or 4)

Hence,
\[
Z_2 = \frac{(24.4 + 24.4) \times 2}{1.15} = \frac{(12.2 + 0.7 \times 27.4)}{1.15} = 54.6 \Omega
\]

Notice how for two track feeding, \((A + R)/R\) above becomes 2, due to a fault current split between two identical parallel paths.

20.8.4.2 ‘Hairpin’ feeding configuration

Referring to Figure 20.8, it is apparent that with only two tracks, inner tracks B and C are not present. Once circuit breaker TF-2 at substation S1 is open, the impedance to the fault is merely 170% times the impedance of track section 1 or 2. Thus, from Equation 20.2:

\[
Z_2 = \left(\frac{24.4 + 0.7 \times 27.4}{1.15}\right) = 36.1 \Omega
\]

For Zone 2 it is always the lower of the two calculated results that is used. Therefore, use a setting of:

Forward reach \( Z_{2\text{fw}} = 36.1 \Omega \)

The Reverse Reach, \( Z_{2\text{bw}} \), is set to Blocked, as only forward directional operation is required.
**20.8.5 Zone 3 Reach Calculation for TF-1**

In similar fashion to the Zone 2 reach, the ‘follow-on’ and ‘Hairpin’ fault configurations have to be considered. As Zone 3 must tend to overreach rather than underreach, 120% of the fault impedance calculated is used as the setting and the higher of the two possible settings is used.

**20.8.5.1 ‘Follow-On’ fault configuration**

Figure 20.9 shows the configuration for a follow-on fault with two tracks: It is apparent that the calculation is exactly as for Zone 2 follow-on, except that the multiplier of 0.7 (70%) is replaced by 1 (100%).

$$Z_3 = (12.2 + 27.4) \times 2 \times 1.2$$

$$= 95.1 \Omega$$

**20.8.5.2 ‘Hairpin feeding’ fault configuration**

Repeating the same for hairpin feeding (Figure 20.10, Equation 20.4):

$$Z_3 = (24.4 + 24.4) \times 1.2$$

$$= 58.6 \Omega$$

Hence, use a setting of:

**Forward reach** $Z_{3fu} = 95.1 \Omega$

For Zone 3, a reverse reach is required to act a backup to the upstream protection. The usual setting is 25% of the Zone 1 forward reach. Therefore, use a setting of:

**Reverse reach** $Z_{3bw} = 0.25 \times 20.75$

$$= 5.2 \Omega$$

**20.8.6 Zone Time Delays**

The Zone 1 time delay will be set to instantaneous operation ($t_1 = 0$) – it is not common practice to time-grade this zone with the primary protection fitted on board the trains.

Zone 2 ($t_2$) should be delayed as follows:

$$t_2 = CB \text{ max trip time } + \text{ Relay max trip time } + 50\text{ms margin}$$

Hence,

$$t_2 = 65 + 45 + 50$$

$$= 160\text{ms}$$

As all of the protection and circuit breakers are identical, this value can be used for $t_2$. If the downstream relays were electromechanical (typically 40–70ms slower than numerical), or the circuit breakers were oil insulated (OCB's, typically 40 to 60ms slower than VCB's), then the $t_2$ delay would need to be extended accordingly. The 50ms margin allows for the reset time of the Z2 element.

The Zone 3 time delay can typically be set double the minimum calculated above. However, as Zone 3 is often most at risk of unwanted pickup due to train starting currents or momentary overloads, a longer setting of $t_3 = 500\text{ms}$ is applied.

**20.8.7 Overcurrent Protection**

Overcurrent protection can be applied to the 25kV system in Figure 20.17. For railway applications, non-directional overcurrent protection is normal. The simplest application is for track feeders at Feeder Stations, such as TF-1. At this location and with normal feeding, any fault current will naturally be flowing away from the busbar, and so no reverse operation can occur. At downstream substations it will not be possible to apply overcurrent protection in a similar way, and any elements enabled would tend to be set with long time delays to ensure that all of the distance protection zones are given sufficient time to trip beforehand.

**20.8.7.1 Back-Up overcurrent (BUOC) at feeder stations**

Should the distance protection be out of service, two BUOC overcurrent elements could be set. Firstly a high set overcurrent element is set to underreach the protected section, mimicking Zone 1 operation. This can be set for instantaneous tripping. Secondly, a lower-set overcurrent element can be applied to complete protection for the TB-1 section, to overreach the end of the protected section at S2. The overcurrent element of the relay would be set accordingly and with a definite time delay.

**20.8.7.2 Calculation of fault current**

In order to determine the overcurrent settings, the fault current measured by TF-1 CT for a fault adjacent to the S2 busbar needs to be calculated. There are two possible configurations to consider:

a. fault current for a fault at the end of section 1, with two tracks in-service

b. current for a fault at the end of section 1, with section 2 isolated for maintenance

For the first configuration, the fault current per track can be calculated as

$$I_{f,1} = \frac{E}{2 \times (Z_t + Z_{sp})}$$

where:

$$E = \text{source voltage} = 26.4\text{kV}$$

$$Z_t = \text{transformer impedance} = 4.5\angle 88^\circ \Omega$$

$$Z_{sp} = \text{parallel impedance of sections 1 and 2} = 9.76\angle 70^\circ \Omega / 2$$
Note that the fault current splits into two parallel paths, fed via TF-1 and TF-2. Hence, the division by 2 in the equation for calculating the per-track current measured by the protection.

Hence,

\[ I_{f1} = 1.4\, \text{kA} \]

For the second configuration,

\[ I_{f2} = \frac{E}{Z_s + Z_s} \]

where:

\[ Z_s = \text{impedance of section } 1 \]

Hence,

\[ I_{f2} = 1.84\, \text{kA} \]

20.8.7.3 Overcurrent setting for BUOC

**Instantaneous stage**

To prevent overreach, set at least 20% above the higher of the two fault scenarios:

\[ I_{\text{inst}} = 1840 \times 1.2 = 2200\, \text{A} \]

The secondary current setting on the relay is found by dividing by the CT ratio:

\[ I'_{\text{inst}} = \frac{2200}{600} = 3.68\, \text{A} \]

20.8.7.4 Overcurrent setting for BUOC definite-time

**Delayed stage**

To ensure complete coverage for short circuits in the protected section, the setting should be no greater than 80% of the lower of the two fault scenarios:

\[ I_{oc} \leq 1400 \times 0.8 = 1100\, \text{A} \]

In terms of secondary quantities,

\[ I'_{oc} = \frac{1100}{600} = 1.86\, \text{A} \]

A time setting no less than the Zone 2 distance time delay would be used, so \( t'_{oc} = 250\, \text{ms} \) is suitable.

All overcurrent protection must have a pickup in excess of the maximum expected load current. Assuming that the maximum overloading would never exceed 150% of CT rating, the \( I_{\text{inst}} \) and \( I_{oc} \) settings are acceptable.

20.8.7.5 Definite Time Overcurrent (DTOC)

It is not general practice to set instantaneous protection elements that are running in parallel to the distance zones. Thus, often just one definite time delayed stage is used. This setting can be applied at all locations, and must be in excess of the maximum load and overload current expected.

\[ I_{\text{dtinst}} \geq 1.5 \times I_{flc} \]

where:

\[ I_{flc} = \text{full load current of feeder} \]

Hence,

\[ I_{\text{dtinst}} = 1.5 \times 600 = 900\, \text{A} \]

Referred to the secondary side of the CT,

\[ I'_{\text{dtinst}} = \frac{900}{600} = 1.5\, \text{A} \]

The time delay applied must be longer than the \( t_3 \) distance zone delay, so \( t'_{\text{dtinst}} \) would be acceptable.

**20.8.8 Thermal Protection**

The thermal data for the catenary are also given in Table 20.1. The calculation of the thermal protection settings is given in the following sections.

**20.8.8.1 Thermal reference current/ temperature**

The P438 requires a thermal rated current or reference current, \( I_{\text{ref}} \) to be set that corresponds to full load current. The ambient temperature at which this applies qualifies this rated current. The reference current referred to the CT primary is given in Table 20.1 as:

\[ I_{\text{refp}} = 540\, \text{A} \]

The relay setting is in terms of the secondary current. Hence, the secondary current setting on the relay is found by dividing by the CT ratio:

\[ I'_{\text{refp}} = \frac{540}{600} = 0.9\, \text{A} \]

The ambient temperature \( t_{\text{amb}} \) at which \( I_{\text{refp}} \) occurs is set at 20°C.

**20.8.8.2 Mechanical damage protection**

The catenary temperature at which mechanical damage may begin to occur is 56°C. This must correspond to the P438 thermal trip command, and so:

\[ t_{\text{catmax}} = 56\, ^\circ\text{C} \]

Account must be taken of the measurement errors described in Section 20.4.1. The P438 relay setting, \( \theta_{\text{trip}} \), must allow for these errors, which are taken to be 4°C. Hence,

\[ \theta_{\text{trip}} = (56 - 4)^\circ\text{C} = 52\, ^\circ\text{C} \]

To avoid chattering of contacts when the load current is close to the trip threshold, a hysteresis setting is provided on reset. Typically the hysteresis is set to 2%, such that following a trip, the thermal model must cool by 2% before the trip contacts will reset.
20.8.8.3 Dewirement protection

An alarm should be issued to warn the rail operator when speed restrictions are necessary, to avoid the risk of dewirements. From Table 20.1, the catenary temperature at which there is a danger of dewirement is 48°C. The same measurement errors apply as for the trip setting. Hence the relay setting, $\theta_{\text{warning}}$, is:

$$\theta_{\text{warning}} = (48 - 4)°C = 44°C$$

20.8.8.4 Maximum ambient temperature

It is possible to place a limit on the maximum ambient temperature that will be used by the thermal model, to avoid over-restrictive loading constraints being imposed. From Table 20.1:

$$t_{\text{ambmax}} = 28°C$$

20.8.8.5 Default ambient temperature

If ambient temperature compensation is not being used, an assumed default coolant temperature ambient must be chosen. The default ambient temperature must be chosen to be sufficiently high to minimise the danger of undetected problems occurring on hot days, when the ambient temperature is well in excess of the default value. Similarly, it must not be so high that alarms and/or trips occur unnecessarily. A default ambient temperature, $t_{\text{ambdef}}$ of 20°C, would provide adequate protection, except for a calculated risk on certain hot summer days. Note that the rated thermal current at this ambient is $I_{\text{refs}}$.

20.8.8.6 Thermal time constants

The catenary thermal model requires heating and cooling time constants to be specified. For most catenaries, the heating and cooling time constants would be expected to be equal. However, this may not always be the case, for example the cooling time constant at night may be longer than that applicable during the day. The relay can accommodate different settings where required. Conservative settings that assume the worst case time constants for heating ($\tau_h$) and cooling ($\tau_c$) would be to assume a daytime heating time constant and nighttime cooling time constant. Hence:

$$\tau_h = 5\text{ min}$$
$$\tau_c = 7\text{ min}$$

The P438 also allows the thermal rating of the protection to be modified, based on signals from opto inputs. However, this facility is not used in this example.

20.8.9 Summary of Catenary Protection Settings

The protection calculations for the catenary are now complete. The relay settings are summarised in Table 20.2.
